Abstract

Objective. This study aims to determine the prevalence of subclinical thyroid dysfunction among cardiac patients at the Philippine General Hospital, and its association with mortality.

Methodology. 163 adult cardiac patients were screened for subclinical thyroid dysfunction, [subclinical hyperthyroidism (SCT), subclinical hypothyroidism (SCHO), non-thyroidal illness syndrome (NTIS)]. Demographic and clinical characteristics were analyzed using ANOVA and Fisher's exact test. Outcome considered were hospital duration, need for mechanical ventilation, inotropic support and mortality. Crude association between subclinical thyroid dysfunction and outcomes was evaluated using relative risk.

Results. Prevalence of subclinical thyroid dysfunction was 32.5% (5.5% SCT, 5.5% SCHO, and 21.5% NTIS). The risk of necessitating mechanical ventilation was about twofold higher in subclinical thyroid dysfunction compared to euthyroid patients (RR=2.64), and was highest in SCHO (RR=3.71). The risk of inotropic support was about twofold higher (RR=2.70) in SCHO compared to euthyroid patients. Overall death rate was higher in subclinical thyroid dysfunction (RR=1.86), and highest in SCHO (RR=2.47) compared to euthyroid patients.

Conclusion. There is a significant prevalence of subclinical thyroid dysfunction among hospitalized patients with cardiac disease at 32.5%. Cardiovascular risk factors are not statistically significant. We observed a trend of increased risk of requiring mechanical ventilation, inotropes and overall mortality in SCHO.

Key words: Subclinical thyroid dysfunction, prevalence, mortality

INTRODUCTION

The effects of overt hyper- or hypothyroidism on the cardiovascular system are well known, but whether subclinical or mild thyroid dysfunctions have clinical significance is still to be proven. A consensus conference on subclinical thyroid disease concluded that there is insufficient evidence whether subclinical thyroid dysfunction is associated with cardiovascular disease and increased mortality.¹

Subclinical hyperthyroidism, defined as a low serum thyroid-stimulating hormone (TSH) concentration in an asymptomatic subject with normal serum triiodothyronine (T₃) and thyroxine (T₄) concentrations, is common in the community, with the prevalence reported to range from 0.5% to 3.9% in adults of all ages and 11.8% in a study among the elderly.^{2,3} On the other hand, subclinical hypothyroidism, defined as an elevated serum TSH level in the background of normal serum T₃ and T₄

values, affects around 4% of the general population and 10% to 15% of older persons.⁴

Non-thyroidal illness syndrome (NTIS) occurs during starvation or critical illness when thyroid hormones in blood are reduced to levels typical of hypothyroidism. Generally, serum T₃ and free T₃ are low, while serum T₄ is likewise reduced in proportion to the severity and length of the illness. This is believed to be due to rapid inhibition of deiodination of T₄ to T₃ by type 1 iodothyronine deiodinase in the liver, causing the inhibition of T₃ generation, as well as prevention of rT₃ metabolism. One of the hallmarks of NTIS is a usually normal or inappropriately suppressed TSH, presumably due to reduced secretion from deficient TRH production.⁵

Relating thyroid dysfunction with deleterious cardiovascular effects is not without basis. Several mechanisms proposed include coronary vascular stenosis induced by local inflammation from autoimmune

thyroiditis, altered serum lipids, increased peripheral vascular resistance associated with subclinical hypothyroidism, and increased risk for atrial fibrillation and other cardiac dysrhythmias among patients with excess thyroid hormones.⁶⁻⁸ These changes translate to increased risk of coronary heart disease events and mortality in the future.

NTIS, low T3 syndrome or sick euthyroid syndrome is believed to be compensatory and is a beneficial response that decreases energy consumption in disease states. This alteration also has a negative prognostic impact, especially among patients with heart disease.^{9,10}

At present, there is paucity of data regarding the prognostic impact of the disease in cardiac patients; and its association with mortality is controversial. One study which included 1026 acute cardiac patients had a 43% prevalence of subclinical thyroid dysfunction, the majority of whom had NTIS (34.7%), the rest had subclinical hypothyroidism (6.6%), and subclinical hyperthyroidism (2.2%). The mortality rate was 22.15% and more than half of the deaths are due to cardiovascular causes. In-hospital mortality of the total population was 3.58%.¹¹

This study was done to determine the institutional prevalence of subclinical thyroid dysfunction among patients with cardiovascular events and its impact on mortality. Recognizing the increased morbidity and fatal outcomes of cardiovascular events, this study will be able to provide additional data regarding recommendations in terms of screening "high risk" patients.

METHODOLOGY

Design

Cross-sectional, and Prospective Cohort Study

Setting

UP-Philippine General Hospital: The investigators identified potential eligible patients from the Emergency room (ER)-Acute Coronary Unit (ACU), Medical Intensive Care Units (MICU), and Medical Wards. Medical records were reviewed prior to blood extraction.

Subjects

The subjects included adult patients (>18 years old) who presented with any of the following cardiovascular events at the acute care unit or the medical wards:

1. **Acute coronary event** (acute myocardial infarction, unstable angina)
ST-segment elevation myocardial infarction (STEMI) was confirmed by the presence of the following: 1) typical chest pain, 2) electrocardiographic findings of ST-segment elevation or Q waves, and 3) elevated

myocardial enzymes. Unstable angina (UA) was defined as angina pectoris or equivalent ischemic discomfort with at least one of three features: 1) occurred at rest (or minimal exertion) usually lasting >10 minutes, 2) severe and of new onset (within the prior 4-6 weeks and/or 3) occurred with a crescendo pattern (i.e. distinctly more severe, prolonged, or frequent than previously). Non-ST-segment elevation myocardial infarction (NSTEMI) was established if a patient with the clinical features of UA developed evidence of myocardial necrosis, as reflected in elevated cardiac biomarkers.

2. **Cardiac dysrhythmias** [atrial fibrillation, complete atrioventricular (AV) block, sick sinus syndrome]
The presence of cardiac dysrhythmias on electrocardiography, such as atrial fibrillation, complete AV block, sick sinus syndrome, were reviewed and confirmed by a cardiology fellow for each case. A 24-hour Holter monitoring or other tests may be done to confirm the diagnosis.
3. **Congestive heart failure (CHF)**
The Framingham Criteria was used for the diagnosis of CHF. At least 1 Major and 2 Minor criteria were required to satisfy the diagnosis. The major criteria include paroxysmal nocturnal dyspnea, neck vein distention, rales, cardiomegaly, acute pulmonary edema, S3 gallop, increased venous pressure (>16 cm H2O), positive hepatjugular reflux. Minor criteria include extremity edema, night cough, dyspnea on exertion, hepatomegaly, pleural effusion, vital capacity reduced by one-third from normal, and tachycardia (>120 bpm). Weight loss >4.5kg over 5 days' treatment was considered either a major or minor criteria.
4. **Pericardial diseases** (pericarditis, pericardial effusion, cardiac tamponade)
Acute and chronic pericarditis was suspected in a patient with a history of pleuritic chest pain and fever, a physical finding of pericardial friction rub and an electrocardiographic finding of widespread ST-elevation with upward concavity. Pericardial effusion, on the other hand, was suspected in a dyspneic patient with muffled heart sounds and note of a patch of dullness beneath the angle of the left scapula (Ewart's sign). Characteristic electrographic findings include low-voltage QRS complexes and "electrical alternans." Confirmation of pericardial effusion or cardiac tamponade was made with note of presence of pericardial fluid as an echo-free space on two-dimensional transthoracic echocardiography.
5. **Hypertensive vascular diseases** (malignant hypertension)
In addition to marked blood pressure elevation (usually diastolic BP > 130 mm Hg) in association with papilledema and retinal hemorrhages or

exudates, malignant hypertension included manifestations of hypertensive encephalopathy such as severe headache, vomiting, transient paralysis, stupor and coma.

Confirmation of the cardiac diagnosis was verified by the actual assessment of the cardiology fellow for each case.

Before the blood extraction, the potential subjects understood and completed the Informed Consent, as explained thoroughly by the investigator before signing. The following baseline data were extracted: patient characteristics (age, sex), associated medical problems (hypertension, diabetes mellitus, dyslipidemia), and other significant cardiac risk factors (family history of sudden cardiac death, smoking).

Exclusion Criteria

All patients who have clinically apparent thyroid disease or already taking thyroid medications (levothyroxine, methimazole, carbimazole, thiamazole, propylthiouracil and potassium iodide) were excluded from the study. Patients taking other medications that could potentially affect thyroid function testing were also excluded. These medications include: dopamine, levodopa, bromocriptine, glucocorticoids (>0.5 mg/day dexamethasone, 100 mg/day hydrocortisone), octreotide, amphetamines, metoclopramide, amiodarone, iodinated contrast media, furosemide (>80 mg/day), nonsteroidal agents (salicylates >2gm/day, salsalate >1.5-3 gm/day, diclofenac, naproxen), IV heparin, phenytoin, and carbamazepine.¹² Pregnant patients were also excluded.

Classification by Thyroid Status

Patients were classified into 1 of the following 6 groups based on their thyroid function tests:¹⁻⁵

1. **Overt thyrotoxicosis** was defined as a TSH concentration of less than 0.10mU/L with an elevated free T4 or free T3
2. **Subclinical hyperthyroidism (SCT)** was defined as a TSH concentration of 0.10mU/L to 0.24mU/L or less than 0.10mU/L with a normal free T4 or free T3
3. **Euthyroidism (EU)** was defined as a normal TSH concentration of 0.25mU/L to 4.0mU/L and normal free T4 and free T3
4. **Subclinical hypothyroidism (SCHO)** was defined as a TSH concentration of more than 4.0mU/L or less than 10mU/L with a normal free T4 or free T3 concentration
5. **Overt hypothyroidism** was defined as a TSH level of more than 10mU/L or more than 5mU/L with a free T4 or free T3 concentration below normal

6. **Nonthyroidal illness syndrome (NTIS)** was defined as low or normal TSH with a low free T4 or low free T3

Study Outcomes

Subjects were followed up until the day of discharge. The outcomes of measure include: hospital duration, need for mechanical ventilation and inotropic support, and all-cause mortality.

Hormonal Measurements

Serum free T₄ and T₃, and TSH concentrations were determined from blood samples drawn immediately after arrival in the emergency department and prior to any intravenous therapy, including administration of heparin. Ascertainment of serum free T₃ and T₄ were accomplished using enzyme immunoassays while TSH utilized the IRMA method. We used study specific cut off values (Manila Endocrine Laboratory) as follows: free T₄ (11.5-23.0 pmol/L), free T₃ (2.5-5.0 pmol/L), and TSH (0.25-4.0 mIU/ml).

Statistical Analysis

The sample size that is required to estimate the prevalence of subclinical thyroid dysfunction is 163, given an estimated prevalence of 12% with 5% error given a 95% confidence interval.^{13,14} Of the 163 patients included in the study, 142 were analyzed. Demographic and clinical characteristics were analyzed as subclinical thyroid dysfunction group (SCT, SCHO and NTIS), and then each subgroup. The crude association between subclinical thyroid dysfunction and outcomes was evaluated using relative risk

RESULTS AND DISCUSSION

The overall prevalence of subclinical thyroid dysfunction among patients with cardiovascular events was 32.5% (53/163), and more than half of the cases have NTIS. (Table 1). There are few reports on the prevalence of the disease among cardiac patients, with varying selective criteria. A study from Italy showed a prevalence rate of 43.6%, and the most frequent subclinical thyroid dysfunction was NTIS at 34.7%. The prevalence of SCHO closely paralleled that of our study (6.6% vs 5.5%).¹¹ At present, there is no local published data available for comparison, however, our study further supports previous findings of high prevalence of the clinical condition as seen in international studies.

In a national survey of thyroid dysfunction in the country, the prevalence was 8.53% in the general population, with the predominant problems being SCT and SCHO.¹⁵ This value appears low, probably because NTIS was not determined in the study, and the majority of participants were middle-aged. The prevalence of SCT in our study

was comparable with that of the general population (5.5% vs. 5.33%).¹⁵ However, it is difficult to compare our findings because of the difference in populations studied.

Knowing the consequences of even mildly altered thyroid hormone status, this study may help clinicians decide whether screening for subclinical thyroid dysfunction is warranted, especially in those with cardiovascular events.

Table 1. Classification of patients according to thyroid function status

Thyroid Function Status	Frequency	Percent (%)
Euthyroidism	89	54.6
Subclinical hyperthyroidism	9	5.5
Subclinical hypothyroidism	9	5.5
Overt thyrotoxicosis	3	1.8
Overt hypothyroidism	7	4.3
Nonthyroidal illness	35	21.5
Unclassified	11	6.7
Total	163	100

The study population was composed mainly of older patients, with about 45% of the sample population aged 60 and above. Males comprised 44.78% of the total population (Table 2.1). Patients with SCT tend to be older (Table 2.2), however, this was not statistically significant. Both SCT and SCHO are known to be more common among women and elderly.^{4,16-19} SCT has been particularly well studied among the elderly population. It is associated with a higher mortality rate in chronically ill geriatric patients (62% versus 28%, $p < 0.05$) and poses a 2.2-fold risk in mortality from all causes and 3-fold in cardiovascular among those aged >60 years old after a single measurement of low TSH.¹⁹ These studies provide evidence for the recommendation on the screening for thyroid dysfunction and treatment of subclinical hyperthyroidism among the elderly.^{20,21}

Cardiovascular risk factors and comorbidities did not statistically differ between euthyroid and subclinical thyroid dysfunction, except for family history of early cardiac death and probably smoking history. (Table 2.1). When further analyzed, this was not found significant in any of the subgroups. On the other hand, history of malignancy was significant, however, the numbers were too small (Table 2.2).

Diabetes is one of the clinical conditions associated with thyroid dysfunction. This has been recognized since 1979,

with subclinical hypothyroidism being the most common.²²⁻²⁵ Thyroid hormones have a direct action in insulin secretion. In hypothyroidism, there is a reduction in glucose-induced insulin secretion by beta cells, while the response of beta cells to glucose or catecholamine is increased in hyperthyroidism due to increased beta cell mass. Moreover, insulin clearance is increased in thyrotoxicosis.^{26,27} SCT in type 2 diabetic patients tend to increase with age and among women, and is associated with an increase cardiovascular disease and mortality.²⁵

Malignancy (n, %)	2 (2.3)	2 (3.8)	0.629

^acomparison by age was done using analysis-of-variance while Fisher's exact test was used for the rest of the variables

In terms of the cardiovascular events, acute myocardial infarction and heart failure comprised more than 50% of the cardiac diagnosis, similar to that seen in the population studied by Molinaro.¹¹ Dysrhythmia was statistically different between the two groups, but no difference was found when further analyzed across the subgroups (Table 3.1 and 3.2).

A low serum TSH concentration is generally a sensitive marker of thyroid hormone excess and has been reported in a large population-based study to be associated with a 3-fold higher risk of developing atrial fibrillation (AF) in the subsequent decade.²⁸ The cumulative incidence of AF after 10 years among subjects with a low TSH concentration (≤ 0.1 mU/liter) was 28%, compared with 11% in those with a normal TSH ($p = 0.005$). The presence of atrial fibrillation predisposes to embolic events, which may contribute to increased vascular mortality among patients with excess thyroid hormones.

Several studies have demonstrated altered thyroid hormone metabolism, particularly low FT4 or FT3, among cardiac patients (i.e., myocardial infarction, heart failure), and is suggested to be an independent predictor of mortality.^{10, 29, 30} Serum T4 below 4 pmol/L is associated with a marked increased risk of death, while a serum T4 below 2 pmol/L denotes an extremely guarded prognosis. On the other hand, increased levels of reverse T3 during admission after a myocardial infarction, is found to be associated with subsequent short-term and long-term mortality, independent of risk factors.³⁰

^aFisher's exact test

Studies on subclinical hypothyroidism and cardiovascular disease have conflicting results. In cohort studies from the United Kingdom, there was no increase in cardiovascular risk among subjects with subclinical hypothyroidism. In contrast, the Rotterdam Study reported an increased prevalence of myocardial infarction among women 55 years or older with subclinical hypothyroidism.³¹ In the longitudinal analysis of subjects with subclinical hypothyroidism, there were 21 cardiovascular deaths observed compared with 9.5 expected (age- and sex-adjusted hazard ratio, 1.5; 95% confidence interval, 1.0-2.4; p=.08) and 33 coronary heart disease events observed compared with 14.7 expected (age- and sex adjusted hazard ratio, 1.7; 95% confidence interval, 1.2- 2.4; p=.01). The increased risk of coronary heart disease events remained significant after further adjustment for standard cardiovascular risk factors.¹³

The risk of requiring the use of mechanical ventilation was higher among patients with subclinical thyroid dysfunction (RR=2.64) compared to euthyroid patients. The risk was highest in SCHO compared to euthyroid patients (RR=3.71). Likewise, the risk of inotropic support was highest (RR=2.70) in SCHO compared to euthyroid patients. Prolonged hospital duration³² did not differ between the two groups. (Table 4.1 and 4.2). Overt hypothyroidism and its milder forms, SCHO and NTIS, result in depressed ventilatory control.³³ Persistent, critically ill patients, often develop muscle dysfunction that is probably due to decreased mitochondrial activity and content.³⁴ Since thyroid hormones are involved in mitochondrial function and biogenesis, the changes may be relevant to the pathogenesis of respiratory failure.³⁵ However, whether this study finding is caused solely by the presence of the thyroid dysfunction, or due to other confounding factors such as comorbidities, sepsis etc., cannot be dismissed.

In terms of in-hospital mortality, 9/52 (17.3%) with subclinical thyroid dysfunction died, compared to 8/87 (9.2%) euthyroid patients. The patient with SCT and 2 with SCHO died of cardiac causes. Among those with NTIS, cardiovascular deaths accounted for 4 patients and non-cardiac deaths for 2 patients. The risk of dying among patients with subclinical thyroid dysfunction as opposed to those who were euthyroid was about twice as high (RR=1.86). The risk was highest among SCHO patients (RR=2.47) (Table 4.1 and 4.2).

In one study, the overall death rate was 12.75%. However, the investigators excluded patients with acute coronary event, pulmonary edema and mainly categorized subjects to have ischemic and non-ischemic heart disease.³⁶ In another study, which closely resembled our present study in selection criteria and outcomes considered, the overall death rate was 22.15%, mainly because there was longer follow up with patients after the hospital admission. Hazard ratios for both cardiac and overall deaths was significantly higher in all patients with subclinical thyroid dysfunction compared to euthyroid patients (1.937, p=0.018; 1.933, p=0.012).¹¹ And consistently, more than half of the patients in each study died of a cardiac cause.

^c comparing NTIS to euthyroid

Different studies have shown that any form of subclinical thyroid dysfunction has a negative prognostic impact among cardiac patients.^{10,11,29,30,36} Although the present results cannot make any significant association between subclinical thyroid dysfunction and adverse clinical outcomes due to our limited sample size, there is a trend towards increased mortality. It is also noteworthy to mention the higher risk in terms of the outcomes (mechanical ventilation, inotrope use and mortality) in the SCHO group. This is an area for further research.

Limitations of the Study

The study only tested thyroid function once, upon evaluation, and cannot account for transient cases of subclinical dysfunction. Ideally, another test, taken 6-8 weeks from admission should have been taken. Also, additional testing to define the nature of the thyroid disease (i.e., ultrasonography, thyroid scintigraphy, antibody determination) should have been done. And because this is an observational study, even after adjusting for multiple variables, the possibility of residual confounding remains.

CONCLUSION

There is a high prevalence of subclinical thyroid dysfunction among patients with cardiovascular events at 32.5%, majority have nonthyroidal illness. The difference in cardiovascular risk factors was not statistically significant. The need for mechanical ventilation and inotropic support were highest in SCHO (RR=3.71, 2.70, respectively) compared to euthyroid. A trend towards increased mortality among patients with subclinical thyroid dysfunction was found (RR=1.86), and the risk was highest in SCHO (RR=2.47) compared to euthyroid.

Articles and any other material published in the JAFES represent the work of the author(s) and should not be construed to reflect the opinions of the Editors or the Publisher. Authors are required to accomplish, sign and submit scanned copies of the JAFES Declaration: that the article represents original material, that is not being considered for publication or has not been published or accepted for publication elsewhere. Consent forms, as appropriate, have been secured for the publication of information about patients; otherwise, authors declared that all means have been exhausted for securing such consent. The authors have signed disclosures that there are no financial or other relationships that might lead to a conflict of interest. All authors are required to submit Authorship Certifications that the manuscript has been read and approved by all authors, and that the requirements for authorship have been met by each author.
